#### Abstract

In this paper, the conditional distance correlation (CDC) is used as a measure of correlation to develop a conditional feature screening procedure given some significant variables for ultrahigh-dimensional data. The proposed procedure is model free and is called conditional distance correlation-sure independence screening (CDCSIS for short). That is, we do not specify any model structure between the response and the predictors, which is appealing in some practical problems of ultrahigh-dimensional data analysis. The sure screening property of the CDC-SIS is proved and a simulation study was conducted to evaluate the finite sample performances. Real data analysis is used to illustrate the proposed method. The results indicate that CDC-SIS performs well.

Keywords Conditional distance correlation • Feature selection • Sure screening property • High-dimensional data

[^0]
## 1 Introduction

With the development of modern technology, the collection and storage of ultrahighdimensional data become easier in various scientific areas, such as genomics, proteomics, and high-frequency finance, where the number of variables $p$ may grow exponentially with the sample size $n$. One way to deal with large $p$ is to use variable selection which assumes that only a small number of predictors are rescaled to the response, that is, the sparsity principle. However, the regulation methods may not perform well for ultrahigh-dimensional data, due to simultaneous challenges of computational expediency, statistical accuracy, and algorithm stability (Fan et al. 2009).

To tackle these difficulties, Fan and Lv (2008) proposed a two-stage procedure. First, a fast screening procedure is applied to reduce the ultrahigh dimensionality to a moderate scale that is smaller than or equal to the sample size $n$; then, regulation method can be used to obtain the final model. Several screening methods have been developed in the recent history. Fan and Lv (2008) introduced a marginal Pearson correlation measure in the linear model. Fan and Song (2010) extended the method to generalized linear model by ranking the maximum marginal likelihood estimates. Furthermore, Fan et al. (2011) explored the feature screening technique for ultrahighdimensional additive models. Zhu et al. (2011) proposed a robust correlation measure under the multi-index model. The methods mentioned above are based on model structures, which may cause incorrect results when the models are misspecified. Recently, Li et al. (2012) proposed a model-free feature screening technique based on the distance correlation (DC) studied in Szekely et al. (2007). This measure is robust to model misspecification and can be used for feature screening without specifying a regression model. Zhong et al. (2016) generalized the DC method to a robust one through the distance correlation between the predictors and the marginal distribution of the response.

In some practical problems, however, some predictors are known to be significant to response. A problem is that how to make feature screening for the remaining predictors given the significant predictors. An analogous problem is considered by Liu et al. (2014), where the conditional Pearson correlation coefficient is used as a measure to develop a conditional feature screening for the linear varying coefficient model. That is, given the exposure variables, the conditional Pearson correlation-based feature screening is developed for the predictors in the linear part. Fan et al. (2014) also proposed a screening method in linear varying coefficient models, that cannot adapt to the nonlinear situations yet.

How to construct a model-free conditional measure to screen the predictors is a very important task. This paper uses the conditional distance correlation (CDC) measure due to Wang et al. (2015) to develop conditional feature screening given some significant variables without assuming any model structure. The proposed procedure is referred to as conditional distance correlation sure independence screening (CDC-SIS for short). Wang et al. (2015) showed that the CDC equals zero if and only if two random vectors are independent conditional on some other variables. We systematically study the theoretical properties of the CDC-SIS and prove that with probability tending to one, all active predictors are selected, i.e., the sure screening property proposed in Fan and

Lv (2008) is proved. The finite sample performances of the proposed procedure via numerical simulation are studied.

The rest of this paper is organized as follows. In Sect. 2, we propose a new conditional feature screening procedure for ultrahigh-dimensional data and study its sure screening property. In Sect. 3, a simulation study is conducted to assess the finite sample performances. In Sect. 4, we illustrate the method through a real data example. The regularity conditions and technical proofs are given in Appendix.

## 2 Independence screening using CDC

### 2.1 The methodology

Let $Y \in R$ denote the response, $W$ some significant predictor vector of $Y$, and $\mathbf{X}=$ $\left(X_{1}, \ldots, X_{p}\right) \in R^{p}$ the remaining $p$-dimensional predictors. To highlight our method, we consider univariate $W$ next without loss of generality. We consider the conditional distribution function of $Y$ given $\mathbf{X}$ and $W$, denoted by $F(y \mid \mathbf{X}, W)=P(Y \leq y \mid \mathbf{X}, W)$. Let

$$
\mathcal{M}_{*}=\left\{j: F(y \mid \mathbf{X}, W) \text { functionally depends on } X_{j}\right\}
$$

be the index set of active predictors and it is natural to assume the sparsity, that is, only a small number of predictors in $\mathbf{X}$ are relevant to $Y$ given $W$. Throughout the paper, we assume the cardinality of $\mathcal{M}_{*}, s_{n}=\left|\mathcal{M}_{*}\right|$ is smaller than the sample size $n$. Next, let us introduce the conditional distance correlation suggested by Wang et al. (2015).

For $t \in R$ and $s \in R$, the conditional joint characteristic function of $X_{j}$ and $Y$ given $W$ is defined as

$$
\begin{equation*}
\Phi_{X_{j}, Y \mid W}(t, s)=E\left(e^{i t X_{j}+i s Y} \mid W\right), \quad j=1, \ldots, p \tag{1}
\end{equation*}
$$

where $i$ is the imaginary unit. In addition, the conditional marginal characteristic functions of $X_{j}$ and $Y$ given $W$ are defined as

$$
\Phi_{X_{j} \mid W}(t)=\Phi_{X_{j}, Y \mid W}(t, 0), \quad \text { and } \quad \Phi_{Y \mid W}(s)=\Phi_{X_{j}, Y \mid W}(0, s), \quad j=1, \ldots, p
$$

Wang et al. (2015) proposed conditional distance correlation for measuring the dependence between two random vectors given another random vector. Specifically, given $W$, the conditional distance of $Y$ and $X_{j}, j=1, \ldots, p$ is defined as

$$
\begin{equation*}
D^{2}\left(X_{j}, Y \mid W\right)=\int\left|\Phi_{X_{j}, Y \mid W}(t, s)-\Phi_{X_{j} \mid W}(t) \Phi_{Y \mid W}(s)\right|^{2} w(t, s) \mathrm{d} t \mathrm{~d} s \tag{2}
\end{equation*}
$$

where $w(t, s)=1 /\left(c_{1}^{2}\|t\|^{2}\|s\|^{2}\right)$, and $c_{d}=\pi^{(1+d) / 2} / \Gamma((1+d) / 2)$. Throughout the article, $\|\cdot\|$ stands for the Euclidean norm.

The conditional distance variance of $X_{j}$ and $Y$ given $W$ are, respectively,

$$
\begin{equation*}
D^{2}\left(X_{j} \mid W\right)=D^{2}\left(X_{j}, X_{j} \mid W\right), D^{2}(Y \mid W)=D^{2}(Y, Y \mid W) \tag{3}
\end{equation*}
$$

Then the conditional distance correlation between $X_{j}$ and $Y$ given $W$ is defined as

$$
\begin{equation*}
\rho^{2}\left(X_{j}, Y \mid W\right)=\frac{D^{2}\left(X_{j}, Y \mid W\right)}{\sqrt{D^{2}\left(X_{j} \mid W\right) D^{2}(Y \mid W)}} \tag{4}
\end{equation*}
$$

Define the marginal utility for feature screening as

$$
\rho_{j 0}^{*}=E\left(\rho^{2}\left(X_{j}, Y \mid W\right)\right), \quad j=1, \ldots, p .
$$

A remarkable property of the marginal utility $\rho_{j 0}^{*}$ is that $\rho_{j 0}^{*}=0$ if and only if $X_{j}$ and $Y$ are independent, conditional on $W$. This measure allows our method to detect any nonlinear relationship between the response and predictors. This implies that when there is a nonlinear relationship between $X_{j}$ and $Y, \rho_{j 0}^{*}$ is far away from zero, while the conditional Pearson correlation proposed by Liu et al. (2014) may be very small and even close to zero because that Pearson correlation can only detect the linear relationship between $X_{j}$ and $Y$.

Suppose that $\left\{\left(\mathbf{X}_{i}, Y_{i}, W_{i}\right), i=1, \ldots, n\right\}$ are independent and identically distributed copies of $(\mathbf{X}, Y, W)$, and $\mathbf{X}_{i}=\left(X_{1 i}, X_{2 i}, \ldots, X_{p i}\right)$. Denote $d_{k l}^{X_{j}}=$ $d\left(X_{j k}, X_{j l}\right)$ as the Euclidean distance of $X_{j k}$ and $X_{j l}$ and, similarly, $d_{k l}^{Y}$ for $Y$. Wang et al. (2015) establishes the following expression:

$$
\begin{equation*}
D^{2}\left(X_{j}, Y \mid W=w\right)=S_{1}(w)+S_{2}(w)-2 S_{3}(w) \tag{5}
\end{equation*}
$$

where $S_{j}(w), j=1,2,3$ are defined as

$$
\begin{aligned}
& S_{1}(w)=E\left(d_{k l}^{X_{j}} d_{k l}^{Y} \mid W_{k}=w, W_{l}=w\right), \\
& S_{2}(w)=E\left(d_{k l}^{X_{j}} \mid W_{k}=w, W_{l}=w\right) E\left(d_{k l}^{Y} \mid W_{k}=w, W_{l}=w\right), \\
& S_{3}(w)=E\left(d_{k l}^{X_{j}} d_{k m}^{Y} \mid W_{k}=w, W_{l}=w, W_{m}=w\right) .
\end{aligned}
$$

To estimate $D^{2}\left(X_{j}, Y \mid W=w\right)$, we only need derive the sample estimators of $S_{j}(w), j=1,2,3$. Clearly, these conditional expectations can be estimated by the kernel smoothing method (Fan and Gijbels 1996). Let $K(\cdot)$ be a given kernel function, $h$ a bandwidth, $a_{k}(w)=K_{h}\left(w-W_{k}\right)=K\left(\left(w-W_{k}\right) / h\right) / h$ and $a(w)=\sum_{k=1}^{n} a_{k}(w)$, then the kernel regression estimates are given by

$$
\begin{aligned}
& \hat{S}_{1}(w)=\sum_{k, l=1}^{n} d_{k l}^{X_{j}} d_{k l}^{Y} a_{k}(w) a_{l}(w) / a^{2}(w), \\
& \hat{S}_{2}(w)=\sum_{k, l=1}^{n} d_{k l}^{X_{j}} a_{k}(w) a_{l}(w) \sum_{k, l=1}^{n} d_{k l}^{Y} a_{k}(w) a_{l}(w) / a^{4}(w), \\
& \hat{S}_{3}(w)=\sum_{k, l, m=1}^{n} d_{k l}^{X_{j}} d_{k m}^{Y} a_{k}(w) a_{l}(w) a_{m}(w) / a^{3}(w)
\end{aligned}
$$

Substituting these estimates into (5), we obtain a nature estimator of $D^{2}\left(X_{j}, Y \mid W=\right.$ $w)$, denoted by $\hat{D}^{2}\left(X_{j}, Y \mid W=w\right)=\hat{S}_{1}(w)+\hat{S}_{2}(w)-2 \hat{S}_{3}(w)$. Similarly, we can define the sample conditional distance variances $\hat{D}^{2}\left(X_{j} \mid W=w\right)$ and $\hat{D}^{2}(Y \mid W=w)$. Accordingly, the sample conditional distance correlation is given by

$$
\begin{equation*}
\hat{\rho}^{2}\left(X_{j}, Y \mid W=w\right)=\frac{\hat{D}^{2}\left(X_{j}, Y \mid W=w\right)}{\sqrt{\hat{D}^{2}\left(X_{j} \mid W=w\right) \hat{D}^{2}(Y \mid W=w)}} \tag{6}
\end{equation*}
$$

which can be seen as a function of $w$, denoted by $\hat{\rho}_{j}^{2}(w)$. We now define an estimate of the marginal utility $\rho_{j 0}^{*}$ as

$$
\hat{\rho}_{j}^{*}=\frac{1}{n} \sum_{i=1}^{n} \hat{\rho}_{j}^{2}\left(W_{i}\right), \quad j=1, \ldots, p
$$

Based on $\hat{\rho}_{j}^{*}$, we select a set of important predictors with large $\hat{\rho}_{j}^{*}$,

$$
\hat{\mathcal{M}}=\left\{j: 1 \leq j \leq p, \hat{\rho}_{j}^{*}>c n^{-\kappa}\right\},
$$

where $c$ and $\kappa$ are prespecified threshold values. However, in practice, we often select the first $d$ largest $\hat{\rho}_{j}^{*}$ with $d$ taken to be smaller than the sample size $n$. Thus, we can reduce the dimensionality of the predictors from $p$ to a moderate scale $d$. Liu et al. (2014) suggested setting $d=\left[n^{4 / 5} / \log \left(n^{4 / 5}\right)\right]$ for ultrahigh-dimensional varying coefficient model, where $[a]$ refers to the integer part of $a$.

### 2.2 Sure screening property

We next study the theoretical properties of the proposed screening procedure CDCSIS.

Theorem 1 Under regularity conditions given in Appendix, suppose the bandwidth $h=O\left(n^{-\gamma}\right)$, where $0<\gamma<1 / 2,0 \leq \kappa<\gamma$, and $\xi$ is a positive constant, then we have

$$
\begin{aligned}
& P\left(\max _{1 \leq j \leq p}\left|\hat{\rho}_{j}^{*}-\rho_{j 0}^{*}\right| \geq c n^{-\kappa}\right) \leq O\left(n p \exp \left(-n^{\gamma-\kappa} / \xi\right)\right), \\
& P\left(\mathcal{M}^{*} \subset \hat{\mathcal{M}}\right) \geq 1-O\left(n s_{n} \exp \left(-n^{\gamma-\kappa} / \xi\right)\right) .
\end{aligned}
$$

Theorem 1 indicates that we can handle the nonpolynomial (NP) dimensionality of order $\log p=o\left(n^{\gamma-\kappa}\right)$. In other words, the tail probability in Theorem 1 is exponentially small. Hence, $\hat{\mathcal{M}}$ can retain all important predictors with probability tending to 1 . The following corollary gives the sure screening property of the CDC-SIS screening.

Corollary 1 Under the conditions of Theorem 1 , when $\log p=o\left(n^{\gamma-\kappa}\right)$, we have that

$$
\begin{array}{r}
P\left(\max _{1 \leq j \leq p}\left|\hat{\rho}_{j}^{*}-\rho_{j 0}^{*}\right| \geq c n^{-\kappa}\right) \rightarrow 0, \quad \text { as } n \rightarrow \infty, \\
P\left(\mathcal{M}^{*} \subset \hat{\mathcal{M}}\right) \rightarrow 1, \quad \text { as } n \rightarrow \infty .
\end{array}
$$

CDC-SIS also provides an alternative to the varying coefficient models, although it is suggested in a general case that we do not require specifying the relationship between $Y$ and $\mathbf{X}$ given $W$.

Remark 1 This proposed method is a nonparametric one and hence depends on the selection of the bandwidth. However, in practice, the bandwidth selection is not so critical since we use $\hat{\rho}_{j}^{*}$, which is the average of $\hat{\rho}_{j}^{2}\left(W_{i}\right)$ for $i=1,2, \ldots, n$ and hence is a global quantity. That is, the method is not sensible to the selection of bandwidth as long as the bandwidth satisfies the condition given for the feature screening property. The explanation is similar to Wang and Rao (2002).

## 3 Numerical studies

In this section, we conducted some numerical studies to evaluate the proposed method CDC-SIS, and compared it with the conditional Pearson correlation coefficient proposed by Liu et al. (2014) (CC-SIS), the nonparametric independence screening (NIS) method proposed by Fan et al. (2014), the SIS method proposed by Fan and Lv (2008), the DC-SIS method proposed by Li et al. (2012) and DC-RoSIS method proposed by Zhong et al. (2016). The last three methods are developed for unconditional feature screening. We compare our method with them to display the benefit of using prior knowledge of some significant predictor. The kernel function is taken to be $K(w)=0.75\left(1-w^{2}\right)_{+}$and the bandwidth is taken to be $h=n^{-1 / 5}$ throughout this paper.

Similar to Liu et al. (2014), the variables $\left(W^{*}, \mathbf{X}^{\top}\right)^{\top}$ are generated from $N(0, \Sigma)$, where $\Sigma$ is a $(p+1) \times(p+1)$ covariance matrix with element $\sigma_{i j}=\rho^{|i-j|}$, $i, j=1, \ldots, p+1$. We consider $\rho=0.4$ and 0.8 , respectively. Then we take $W=\Phi\left(W^{*}\right)$, where $\Phi(\cdot)$ is the cumulative distribution function of the standard normal distribution. Thus, $W$ follows a uniform distribution $U(0,1)$ and is correlated with $\mathbf{X}$. We take $p$ to be 1000 , and the sample size $n$ is 200; the model size $d$ is chosen to be $d_{i}=i\left[n^{4 / 5} / \log \left(n^{4 / 5}\right)\right], i=1,2,3$, where $[a]$ denotes the integer part of $a$. All the simulations are based on 500 replications.

Following Li et al. (2012), we employ $S, P_{j}$ and $P_{\text {All }}$ to assess the performance of the CDC-SIS, where $S, P_{j}$ and $P_{\text {All }}$ are defined as follows:

- $S$ : The minimal model size to include all active predictors. We report the 5, 25, 50,75 , and $95 \%$ quantiles of $S$ out of 500 replications.
- $P_{j}$ : The proportion of the $j$-th active predictor selected by the submodel $\hat{\mathcal{M}}$ with size $d$ among 500 replications.
- $P_{\text {All }}$ : The proportion of all active predictors selected by the submodel $\hat{\mathcal{M}}$ with size $d$ among 500 replications.

Example 1 In this example, we consider the following linear varying coefficient model:

$$
\begin{aligned}
(1.1): Y= & \beta_{2}(W) X_{2}+\beta_{100}(W) X_{100}+\beta_{400}(W) X_{400}+\beta_{600}(W) X_{600} \\
& +\beta_{1000}(W) X_{1000}+\epsilon,
\end{aligned}
$$

where the nonzero coefficient functions are defined by

$$
\begin{aligned}
\beta_{2}(W) & =2 I(W>0.4), \quad \beta_{100}(W)=1+W, \quad \beta_{400}(W)=(2-3 W)^{2}, \\
\beta_{600}(W) & =2 \sin (2 \pi W), \quad \beta_{1000}(W)=\exp (W /(W+1)) .
\end{aligned}
$$

We consider two error distributions, a standard norm $N(0,1)$ and a standard Cauchy distribution which has a heavy tail.

Table 1 reports the quantile of $S$. It is seen that, when the model is indeed linear with a norm error, CDC-SIS has a comparable performance to CC-SIS and both outperform the unconditional methods SIS, DC-SIS and DC-RoSIS significantly. The NIS method performs a little bit worse. On the other hand, when the error distribution is heavily tailed, our method clearly outperforms the other methods. It is reasonable because the proposed method is model free, while CC-SIS and NIS are developed for linear varying coefficient model and are not robust to models with heavy tail error distribution. The unconditional methods are intuitively inefficient because they do not use the information of the significant(conditional) predictor. Table 2 reports the proportion $P_{j}$ and $P_{\text {All }}$. All $P_{j}$ and $P_{\text {All }}$ of CDC-SIS are close to 1 as $d$ increases, while the low value of $P_{600}$ and $P_{\text {All }}$ of the SIS, DC-SIS and DC-RoSIS imply that they rank $X_{600}$ behind and regard it as an unimportant variable. This may be because that $\beta_{600}(W)=2 \sin (2 \pi W)$ has mean 0 if $W$ follows a $U(0,1)$ distribution. Thus, the screening methods SIS, DC-SIS and DC-RoSIS are not suitable for varying the coefficient model, especially when the coefficient oscillates about zero.

Example 2 Similar to Example 1, we set

$$
\begin{aligned}
& \beta_{1}(W)=2 I(W>0.4), \quad \beta_{2}(W)=1+W \\
& \beta_{3}(W)=(2-3 W)^{2}, \quad \beta_{4}(W)=2 \sin (2 \pi W)
\end{aligned}
$$

and the error $\epsilon$ follows a standard normal distribution. The response is generated from the following three models.
(2.1) : $Y=\beta_{1}(W) X_{1}+\beta_{2}(W) X_{2}+\beta_{3}(W) I\left(X_{12}<0\right)+\beta_{4}(W) X_{22}+\epsilon$,
(2.2) : $Y=\beta_{1}(W) X_{1} X_{2}+\beta_{3}(W) I\left(X_{12}<0\right)+\beta_{4}(W) X_{22}+\epsilon$,
(2.3) : $Y=\beta_{1}(W) X_{1}+\beta_{2}(W) X_{2}+\beta_{3}(W) I\left(X_{12}<0\right)+\exp \left(\left|X_{22}\right|\right) \epsilon$,
where $I\left(X_{12}<0\right)$ is an indicator function.
Models (2.1)-(2.3) are all nonlinear in $X_{12}$, and model (2.2) contains an interaction term $X_{1} X_{2}$, and model (2.3) is heteroscedastic. However, the CC-SIS and NIS

methods which perform well in linear varying coefficient model are not suitable in these nonlinear cases. The quantile of $S$ is reported in Table 3. We can see that CDCSIS performs better than the other five screening methods, in particular when models deviate far from the linear model. $P_{j}$ and $P_{\text {All }}$ are reported in Table 4. The performance of CC-SIS is not too bad in model (2.1). $P_{1}, P_{2}$ and $P_{22}$ are all equal to 1 , and $P_{12}$ is a little lower, that is because $X_{1}, X_{2}, X_{22}$ are the linear parts, and $X_{12}$ is the nonlinear part of the response. However, CC-SIS has little chance to identify the important predictors $X_{1}, X_{2}$ in model (2.2) and $X_{12}, X_{22}$ in model (2.3). NIS has a poor performance, mainly because the predictor $X_{12}$ presents in an index function, and NIS cannot find it out. The other three unconditional methods clearly cannot select all important predictors with the nonlinear and varying coefficient interaction.

In this paper, we only consider univariate $W$, however, $W$ can be extended to multivariate very directly. In this subsection, we study the applicability of the proposed method in the case of multivariate $W$.

Example $3 \quad Y=\beta_{1}\left(\mathbf{W}^{\top} \gamma\right) X_{1} X_{2}+\beta_{2}\left(\mathbf{W}^{\top} \gamma\right) I\left(X_{3}<0\right)+\epsilon$, with $\mathbf{W}=\left(W_{1}, W_{2}\right)^{\top}$ is a two-dimensional index vector, $\gamma=[1,1]^{\top}$ is the index coefficient, and $\left(\mathbf{W}^{\top}, \mathbf{X}^{\top}\right)^{\top}$ are generated as described before with $\rho=0.4$. Set

$$
\beta_{1}(u)=\exp (5 u) /(1+\exp (5 u)), \quad \beta_{2}(u)=\sin (\pi u)
$$

and the error $\epsilon$ follows a standard normal distribution.
We compare the performances of different methods in Tables 5 and 6. Similar to Example 2, in terms of the quantile of $S$, the size of CDC-SIS is much smaller than the others; on the other hand, the proportion $P_{j}$ and $P_{\text {All }}$ are much closer to 1. In summary, CDC-SIS outperforms the other methods in the case of multivariate $W$ setup under consideration.

Based on the referees' suggestions, we further consider a simulation setup which satisfies the assumptions for the NIS. The results are listed in the supplement with the same setting as in Example 3 in Fan et al. (2014). The results show that CDC-SIS, CC-SIS and NIS perform well and behave better than the unconditional screening methods SIS, DC-SIS and DC-RoSIS. NIS behaves comparably to CDC-SIS and CC-SIS according to the top $50 \%$ quantiles of $S$. However, in terms of the 75 and 95\% quantiles of $S$, the NIS method needs a larger model size to include all active predictors than the CDC-SIS and CC-SIS methods. Moreover, $P_{\text {All }}$ of NIS is a little lower than those of CDC-SIS and CC-SIS, but all these three methods outperform the unconditional screening methods significantly. For more details, please see the supplemental material.

## 4 Real data analysis

In this section, we illustrate the performance of our method through a real data analysis on Boston Housing Data (Harrison and Rubinfeld 1978). The sample size $n=506$ in

this dataset. We treat MEDV (the median value of owner-occupied homes) as response, and $\log$ (DIS) (the weighted distances to five Boston employment centres) as the significant variable. It is reasonable because the geographical accessibility to employment is an important factor to consider when buying houses. The other 13 predictors are included, such as CRIM (per capita crime rate by town), NOX (nitric oxides concentration), LSTAT (lower status of the population) and so on.

Inspired by Fan et al. (2014), to evaluate our method in a high-dimensional setting, we expand the dataset by adding the artificial predictors:

$$
X_{j}=\frac{Z_{j}+t U}{1+t}, \quad j=14,15, \ldots, p
$$

where $p=1000, t=2$, and $Z_{j}, j=14,15, \ldots, p$ are i.i.d. standard normal variables and $U$ follows the standard uniform distribution. In this artificial example, we repeat the experiment 500 times. The results given in Table 7 are very appealing because our method can rank the 13 active variables before the artificial predictors. This implies that our method is very useful in high-dimensional data analysis.

## Appendix

We first establish the following regularity conditions:
(C1) Denote the density function of $W$ by $f(\cdot)$, and assume that it has continuous second derivatives. The support of $W$ is assumed to be bounded and is denoted by $\mathcal{W}=[a, b]$ with finite constants $a$ and $b$.
(C2) $K(\cdot)$ is a symmetric density function with bounded support and bounded over its support.

(C3) The random variables $\mathbf{X}$ and $Y$ satisfy the sub-exponential tail probability uniformly in $p$. That is, there exists a positive constant $s_{0}$, such that for $0 \leq s<s_{0}$,

$$
\begin{array}{r}
\sup _{W \in \mathcal{W}} \max _{1 \leq j \leq p} E\left(\exp \left(s X_{j}^{2} \mid W\right)\right)<\infty \\
\sup _{W \in \mathcal{W}} E\left(\exp \left(s Y^{2} \mid W\right)\right)<\infty
\end{array}
$$

(C4) $\min _{j \in \mathcal{M}^{*}} \rho_{j 0}^{*} \geq 2 c n^{-\kappa}$ for some constant $c>0$ and $0 \leq \kappa<1 / 2$.
Proof of Theorem 1 The proof consists of three steps. We denote the positive constants $c$ and $C$ as generic constants depending on the context, which can vary from line to line.

Step 1. For some $0 \leq \kappa<1 / 2$, we first prove

$$
\begin{gather*}
\max _{1 \leq j \leq p} \sup _{w \in[a, b]} P\left(\left|\hat{\rho}^{2}\left(X_{j}, Y \mid W=w\right)-\rho^{2}\left(X_{j}, Y \mid W=w\right)\right|\right. \\
\left.\geq c n^{-\kappa}\right) \leq C \exp \left(-\frac{n^{-\kappa}}{C h}\right) \tag{7}
\end{gather*}
$$

Refer to the Supplemental material for the proof of Step 1.
Step 2. We prove $P\left(\max _{1 \leq j \leq p}\left|\hat{\rho}_{j}^{*}-\rho_{j 0}^{*}\right| \geq c n^{-k}\right) \leq O\left(n p \exp \left(-n^{\gamma-\kappa} / \xi\right)\right)$.
Note that

$$
\begin{aligned}
P\left(\left|\hat{\rho}_{j}^{*}-\rho_{j 0}^{*}\right| \geq c n^{-\kappa}\right) & \leq P\left(\left|\hat{\rho}_{j}^{*}-\rho_{j}^{*}\right|+\left|\rho_{j}^{*}-\rho_{j 0}^{*}\right| \geq c n^{-\kappa}\right) \\
& \leq P\left(\left|\hat{\rho}_{j}^{*}-\rho_{j}^{*}\right| \geq c n^{-\kappa} / 2\right)+P\left(\left|\rho_{j}^{*}-\rho_{j 0}^{*}\right| \geq c n^{-\kappa} / 2\right)
\end{aligned}
$$

By the definitions of $\hat{\rho}_{j}^{*}, \rho_{j}^{*}=\frac{1}{n} \sum_{i=1}^{n} \rho_{j}^{2}\left(W_{i}\right)$ with $\rho_{j}^{2}(w)=\rho^{2}\left(X_{j}, Y \mid W=\right.$ $w)$ and the result of Step 1, we have, for $j=1,2, \ldots, p$

$$
\begin{align*}
P\left(\left|\hat{\rho}_{j}^{*}-\rho_{j}^{*}\right| \geq c n^{-\kappa} / 2\right) & =P\left(\left|\frac{1}{n} \sum_{i=1}^{n} \hat{\rho}_{j}^{2}\left(W_{i}\right)-\frac{1}{n} \sum_{i=1}^{n} \rho_{j}^{2}\left(W_{i}\right)\right| \geq c n^{-\kappa} / 2\right) \\
& \leq \sum_{i=1}^{n} P\left(\left|\hat{\rho}_{j}^{2}\left(W_{i}\right)-\rho_{j}^{2}\left(W_{i}\right)\right| \geq c n^{-\kappa} / 2\right) \\
& \leq C n \exp \left(-\frac{n^{-\kappa}}{C h}\right) \\
& =O\left(n \exp \left(-n^{\gamma-\kappa} / \xi\right)\right) \tag{8}
\end{align*}
$$

where $\xi$ is a positive constant, and $0 \leq \kappa<\gamma$. By Hoeffding's inequality, for $j=1,2, \ldots, p$, it follows that

$$
\begin{align*}
P\left(\left|\rho_{j}^{*}-\rho_{j 0}^{*}\right| \geq c n^{-\kappa} / 2\right) & =P\left(\left|\frac{1}{n} \sum_{i=1}^{n} \rho_{j}^{2}\left(W_{i}\right)-E \rho_{j}^{2}\left(W_{i}\right)\right| \geq c n^{-\kappa} / 2\right) \\
& \left.\leq 2 \exp \left(-n c^{2} n^{-2 \kappa} / 2\right)\right)=O\left(\exp \left(-n^{1-2 \kappa} / \xi\right)\right) \tag{9}
\end{align*}
$$

Eq. (8) dominates Eq. (9). Hence, for $j=1,2, \ldots, p$, we get

$$
P\left(\left|\hat{\rho}_{j}^{*}-\rho_{j 0}^{*}\right| \geq c n^{-\kappa}\right) \leq O\left(n \exp \left(-n^{\gamma-\kappa} / \xi\right)\right)
$$

We thus have

$$
P\left(\max _{1 \leq j \leq p}\left|\hat{\rho}_{j}^{*}-\rho_{j 0}^{*}\right| \geq c n^{-k}\right) \leq O\left(n p \exp \left(-n^{\gamma-\kappa} / \xi\right)\right)
$$

Step 3. We prove $P\left(\mathcal{M}^{*} \subset \hat{\mathcal{M}}\right) \geq 1-O\left(n s_{n} \exp \left(-n^{\gamma-\kappa} / \xi\right)\right)$.
If $\mathcal{M}^{*} \not \subset \hat{\mathcal{M}}$, then there exist some $j \in \mathcal{M}^{*}$ such that $\hat{\rho}_{j}^{*}<c n^{-\kappa}$, due to $\min _{j \in \mathcal{M}^{*}} \rho_{j 0}^{*} \geq 2 c n^{-\kappa},\left|\hat{\rho}_{j}^{*}-\rho_{j 0}^{*}\right| \geq c n^{-\kappa}$ for some $j \in \mathcal{M}^{*}$, indicating that

$$
\left\{\mathcal{M}^{*} \not \subset \hat{\mathcal{M}}\right\} \subset\left\{\left|\hat{\rho}_{j}^{*}-\rho_{j 0}^{*}\right| \geq c n^{-\kappa} \quad \text { for some } j \in \mathcal{M}^{*}\right\}
$$

## Consequently,

$$
\begin{aligned}
P\left\{\mathcal{M}^{*} \subset \hat{\mathcal{M}}\right\} & \geq P\left\{\max _{j \in \mathcal{M}^{*}}\left|\hat{\rho}_{j}^{*}-\rho_{j 0}^{*}\right|<c n^{-\kappa}\right\} \\
& =1-P\left\{\max _{j \in \mathcal{M}^{*}}\left|\hat{\rho}_{j}^{*}-\rho_{j 0}^{*}\right| \geq c n^{-\kappa}\right\} \\
& \geq 1-s_{n} P\left\{\left|\hat{\rho}_{j}^{*}-\rho_{j 0}^{*}\right| \geq c n^{-\kappa}\right\} \\
& \geq 1-O\left(n s_{n} \exp \left(-n^{\gamma-\kappa} / \xi\right)\right) .
\end{aligned}
$$
